```

Table 1: Mean for different n values.

Method	10	25	50	100	200	400
Monte Carlo	0.987	0.995	1.005	1.002	0.998	0.998
Parametric	1.434	0.856	0.844	0.781	0.851	0.921
Non-Parametric	1.305	0.818	0.815	0.776	0.851	0.920

```
knitr::kable(var_res_df,
              format = "markdown",
              caption = "Variance for different n values.")
```

Table 2: Variance for different n values.

Method	10	25	50	100	200	400
Monte Carlo	0.230	0.080	0.040	0.020	0.010	0.005
Parametric	0.486	0.059	0.028	0.012	0.007	0.004
Non-Parametric	0.225	0.061	0.020	0.011	0.007	0.004

- (d) Carefully discuss your findings; specifically, accuracy (bias and variance) and merits/drawbacks of parametric vs nonparametric bootstrap. You can treat the results of the Monte Carlo-based inference (under simulation from the true distribution) as the golden standard, against which the parametric and nonparametric bootstrap results are compared.

        # print(paste("A:",as.character(Ai),"))")
        # print(paste("C:",as.character(Ci),"))")
        # print(paste("R:",as.character(Ri),"))")

```

```

        # print(paste("FPR = ", FPR))
        # print(paste("TPR = ", TPR))
        # print(paste("G = ", G))
        # print("-----")

    }
}

}
}

results_df = data.frame(x_vec,
                        A_vec,
                        C_vec,
                        R_vec,
                        FPR_vec,
                        TPR_vec,
                        G_vec)

results_df$design_id <- paste(results_df$A_vec,
                             results_df$C_vec,
                             results_df$R_vec)

# Objective function score visualization
plot(x=results_df$x_vec,
     y=results_df$G_vec,
     col=factor(results_df$design_id),
     ylab="G (misclassification cost)",
     xlab="x (FPR)")

```

The best classifier is the one that minimizes the objective function the best over values of  $x$ . In this case it was one with the design combinations of (A:1 C1: R:2) or (A:2 C1: R:2). For higher values of  $x$  an unbalanced population gives higher values from the objective function. A1 is thus better with even populations when. This is because with an uneven class ratio the mis-classification rate increases for higher values of  $x$  because a higher  $x$  value means a higher false positive count. Even when the false negative count is low. This classifier is therefore not stable for all values of  $x$  and we choose the (A:1 C1: R:2) combination over the (A:2 C1: R:2) combination. Even though the (A:2 C1: R:2) combination clearly performs better at lower values of  $x$ . This in turn increased the mis-classifications calculated in the objective function. All classifiers that had a cfn that was 10 times the cfp resulted in an objective function that was orders of magnitude larger than the other classifiers. This makes intuitive sense as it dramatically increases the net cost of mis-classifications. With a TPR that is square rooted the objective function consistently returns a lower mis-classifications score. R2 is thus better. This is because, when the square root of the TPR is used to derive True positives they are higher than when the TPR is not square rooted. This in turn decreases the amount of mis-classifications.

## Problem 6

```
# Generate data
set.seed(0)
n_vec = c(25, 50, 100, 200, 400, 800)
